**Machine
Learning**

Book

Andriy Burkov

“All models are wrong, but some are useful.”
— *George Box*

The book is distributed on the “read first, buy later” principle.

5 Basic Practice

Until now, we only mentioned in passing some problems a data analyst can encounter when working on a **machine learning problem**: **feature engineering**, **overfitting**, **hyperparameter tuning**. In this chapter, we will talk about these and other challenges that have to be addressed before you can type `model = LogisticRegression().fit(x,y)` in scikit-learn.

5.1 Feature Engineering

When a product manager tells you “We need to be able to predict for a customer whether they will stay with us. Here are the logs of customers’ interactions with our product for five years.” you cannot just grab the data, load it into a library and get a prediction. You need to build a **dataset** first.

Remember from the first chapter that the dataset is the collection of **labeled examples** $\{(\mathbf{x}_i, y_i)\}_{i=1}^N$. Each element \mathbf{x}_i among N is called a **feature vector**. A feature vector is a vector in which each dimension $j = 1, \dots, D$ contains a value that describes the example somehow. That value is called a **feature** and is denoted as $x^{(j)}$.

The problem of transforming raw data into a dataset is called **feature engineering**. For most practical problems, feature engineering is a labor-intensive process that demands from the data analyst a lot of creativity and, preferably, domain knowledge.

For example, to transform the logs of user interaction with a computer system, one could create features that contain information about the user and various statistics extracted from the logs. For each user, one feature would contain the price of the subscription; other features would contain the frequency of connections per day, per week and per year. Another feature would contain the average session duration in seconds. Another one would contain the average response time for one request, and so on, and so forth. Everything measurable can be used as a feature. The role of the data analyst is to create *informative* features: those would allow the learning algorithm to build a model that predicts well labels of the data used for training. Highly informative features are also called features with high *predictive power*. For example, the average duration of a user’s session has high predictive power for the problem of predicting whether the user will keep using the application in the future.

We say that a model has a **low bias** when it predicts well the training data. That is, the model makes few mistakes when we try to predict labels of the examples used to build the model.

5.1.1 One-Hot Encoding

Some learning algorithms can only work with numerical feature vectors. When some feature in your dataset is categorical, like “colors” or “days of the week”, you can transform such a categorical feature into several binary ones.

If your example has a categorical feature “colors” and this feature has three possible values: “red”, “yellow”, “green”, you can transform this feature into a vector of three numerical values:

$$\begin{aligned} \text{red} &= [1, 0, 0] \\ \text{yellow} &= [0, 1, 0] \\ \text{green} &= [0, 0, 1] \end{aligned} \tag{1}$$

By doing so, you increase the dimensionality of your feature vectors. You should not transform red into 1, yellow into 2, and green into 3 to avoid increasing the dimensionality because that would imply that there’s an order among the values in this category and this specific order is important for the decision making. If the order of a feature’s values is not important, using ordered numbers as values is likely to confuse the learning algorithm¹.

5.1.2 Binning

An opposite situation, occurring less frequently in practice, is when you have a numerical feature but you want to convert it into a categorical one. **Binning** (also called **bucketing**) is the process of converting a continuous feature into multiple binary features called bins or buckets, typically based on value range. For example, instead of representing age as a single real-valued feature, the analyst could chop ranges of age into discrete bins: all ages between 0 and 5 years-old could be put into one bin, 6 to 10 years-old could be in the second bin, 11 to 15 years-old could be in the third bin, and so on.

Let in our examples the feature $j = 18$ represents age. By applying binning, we replace this feature with the corresponding bins. Let the new three bins, “age_bin1”, “age_bin2” and “age_bin3” were added with indexes $j = 123$, $j = 124$ and $j = 125$ respectively. Now if $x_i^{(18)} = 7$ for some example \mathbf{x}_i , then we set feature $x_i^{(124)}$ to 1; if $x_i^{(18)} = 13$, then we set feature $x_i^{(125)}$ to 1, and so on.

In some cases, a carefully designed binning can help the learning algorithm to learn using fewer examples. It happens because we give a “hint” to the learning algorithm that if the value of a feature falls within a specific range, the exact value of the feature doesn’t matter.

5.1.3 Normalization

Normalization is the process of converting an actual range of values which a numerical feature can take, into a standard range of values, typically in the interval $[-1, 1]$ or $[0, 1]$.

¹When the ordering of values of some categorical variable matters, we can replace those values by numbers by keeping only one variable. For example, if our variable represents the quality of an article, and the values are {poor, decent, good, excellent}, then we could replace those categories by numbers, for example, {1, 2, 3, 4}.

For example, suppose the natural range of a certain feature is 350 to 1450. By subtracting 350 from every value of the feature, and dividing the result by 1100, one can normalize those values into the range $[0, 1]$.

More generally, the normalization formula looks like this:

$$\tilde{x}^{(j)} = \frac{x^{(j)} - \min^{(j)}}{\max^{(j)} - \min^{(j)}},$$

where $\min^{(j)}$ and $\max^{(j)}$ are, respectively, the minimum and the maximum value of the feature j in the dataset.

Why do we normalize? Normalizing the data is not a strict requirement. However, in practice, it can lead to an increased speed of learning. Remember the gradient descent example from the previous chapter. Imagine we have a two-dimensional feature vector. When we update the parameters of w^1 and w^2 , we use partial derivatives of the average squared error with respect to w^1 and w^2 . If x^1 is in the range $[0, 1000]$ and x^2 the range $[0, 0.0001]$, then the derivative with respect to a larger feature will dominate the update.

Additionally, it's useful to ensure that our inputs are roughly in the same relatively small range to avoid problems which computers have when working with very small or very big numbers (known as numerical overflow).

5.1.4 Standardization

Standardization (or **z-score normalization**) is the procedure during which the feature values are rescaled so that they have the properties of a *standard normal distribution* with $\mu = 0$ and $\sigma = 1$, where μ is the mean (the average value of the feature, averaged over all examples in the dataset) and σ is the standard deviation from the mean.

Standard scores (or z-scores) of features are calculated as follows:

$$\hat{x}^{(j)} = \frac{x^{(j)} - \mu^{(j)}}{\sigma^{(j)}}.$$

You may ask when you should use normalization and when standardization. There's no definitive answer to this question. Usually, if your dataset is not too big and you have time, you can try both and see which one performs better for your task.

If you don't have time to run multiple experiments, as a rule of thumb:

- unsupervised learning algorithms, in practice, more often benefit from standardization than from normalization;
- standardization is also preferred for a feature if the values this feature takes are distributed close to a normal distribution (so-called bell curve);

- again, standardization is preferred for a feature if it can sometimes have extremely high or low values (outliers); this is because normalization will “squeeze” the normal values into a very small range;
- in all other cases, normalization is preferable.

Modern implementations of the learning algorithms, which you can find in popular libraries, are robust to features lying in different ranges. Feature rescaling is usually beneficial to most learning algorithms, but in many cases, the model will still be good when trained from the original features.

5.1.5 Dealing with Missing Features

In some cases, the data comes to the analyst in the form of a dataset with features already defined. In some examples, values of some features can be missing. This often happens when the dataset was handcrafted and the person working on it forgot to fill some values or didn’t get them measured at all.

The typical approaches of dealing with missing values for a feature include:

- Removing the examples with missing features from the dataset. This can be done if your dataset is big enough so you can sacrifice some training examples.
- Using a learning algorithm that can deal with missing feature values (depends on the library and a specific implementation of the algorithm).
- Using a data imputation technique.

5.1.6 Data Imputation Techniques

One technique consists in replacing the missing value of a feature by an average value of this feature in the dataset:

$$\hat{x}^{(j)} = \frac{1}{N} x^{(j)}.$$

Another technique is to replace the missing value by the same value outside the normal range of values. For example, if the normal range is $[0, 1]$, then you can set the missing value equal to 2 or -1 . The idea is that the learning algorithm will learn what is it better to do when there’s a missing value – a value significantly different from other values. Alternatively, you can replace the missing value by a value in the middle of the range. For example, if the range for a feature is $[-1, 1]$ you can set the missing value to be equal to 0. Here, the idea is that if we use the value in the middle of the range to replace missing features, such value will not significantly affect the prediction.

A more advanced technique is to use the missing value as the target variable for a regression problem. You can use all remaining features $[x_i^{(1)}, x_i^{(2)}, \dots, x_i^{(j-1)}, x_i^{(j+1)}, \dots, x_i^{(D)}]$ to form a feature vector $\hat{\mathbf{x}}_i$, set $\hat{y}_i = x_i^{(j)}$, where j is the feature with a missing value. Now we can build a regression model to predict \hat{y} from the feature vectors $\hat{\mathbf{x}}$. Of course, to build training

examples $(\hat{\mathbf{x}}, \hat{y})$ you only use those examples from the original dataset, in which the value of feature j is present.

At prediction time, if your example is not complete, you should use exactly the same data imputation technique to fill the missing features as the technique you used to complete the training data.

Before you start working on the learning problem, you cannot tell which data imputation technique will work the best. Try several techniques, build several models and select the one that works the best.

5.2 Learning Algorithm Selection

Choosing a machine learning algorithm can be a difficult task. If you have a lot of time, you can just try all of them. However, usually the time you have to solve a problem is limited. You can ask yourself several questions before starting to work on the problem. Depending on your answers, you can shortlist some algorithms and try them on your data.

- **Explainability**

Does your model have to be explainable to a non-technical audience? Most very accurate learning algorithms are so-called “**black boxes**”. They learn models that make very few errors, but why a model made a specific prediction could be very hard to understand and even harder to explain. Examples of such models are neural networks or ensemble models.

On the other hand, kNN, linear regression, or decision tree learning algorithms produce models that are not always the most accurate, however, the way they make their prediction is very straightforward.

- **In-memory vs out-of-memory**

Can your dataset be fully loaded into the RAM of your server or personal computer? If yes, then you can choose from a wide variety of algorithms. Otherwise, you would prefer **incremental learning algorithms** that can improve the model by adding more data gradually.

- **Number of features and examples**

How many training examples do you have in your dataset? How many features does each example have? Some algorithms, like **neural networks** and **gradient boosting** (we will consider both later) can handle a huge number of examples and millions of features. Others, like SVM, can be very modest in their capacity.

- **Categorical vs numerical features**

Is your data composed of categorical only, or numerical only features, or a mix of both? Depending on your answer, some algorithms cannot handle your dataset directly and you

would need to convert your categorical features into numerical ones by using some techniques like one-hot encoding.

- **Nonlinearity of the data**

Is your data linearly separable or can be modeled using a linear model? If yes, SVM with the linear kernel, logistic regression or linear regression can be a good choice. Otherwise, deep neural networks or ensemble algorithms, discussed in Chapters 6 and 7, might work better for your data.

- **Training speed**

How much time a learning algorithm is allowed to use to build a model? Neural networks are known to be slow to train. Simple algorithms like logistic and linear regression as well as decision tree learning are much faster. Some specialized libraries contain very efficient implementations of some algorithms; you may prefer to make a research online to find such libraries. Some algorithms, such as random forests, benefit from the availability of multiple CPU cores, so their model building time can be significantly reduced on a machine with dozens of CPU cores.

- **Prediction speed**

How fast does the model have to be when generating predictions? Will your model be used in production where a very high throughput is required? Some algorithms, like SVMs, linear and logistic regression, or some types of neural networks, are extremely fast at the prediction time. Some others, like kNN, ensemble algorithms and very deep or recurrent neural networks, can be slower².

If you don't want to guess the best algorithm for your data, a popular way to choose one is by testing it on the **validation set**. We will talk about that below.

Alternatively, if you use scikit-learn, you could try their algorithm selection diagram shown in fig. 1.

5.3 Three Sets

Until now, we used the expressions “dataset” and “training set” interchangeably. However, in practice data analysts work with three sets of labeled examples:

- 1) training set,
- 2) validation set, and
- 3) test set.

Once you have got your annotated dataset, the first thing you do is you shuffle the examples and split the dataset into three subsets: training, validation, and test. The training set is

²The prediction speeds of kNN and ensemble methods implemented in the modern libraries are still very fast. Don't be afraid of using these algorithms in your practice.

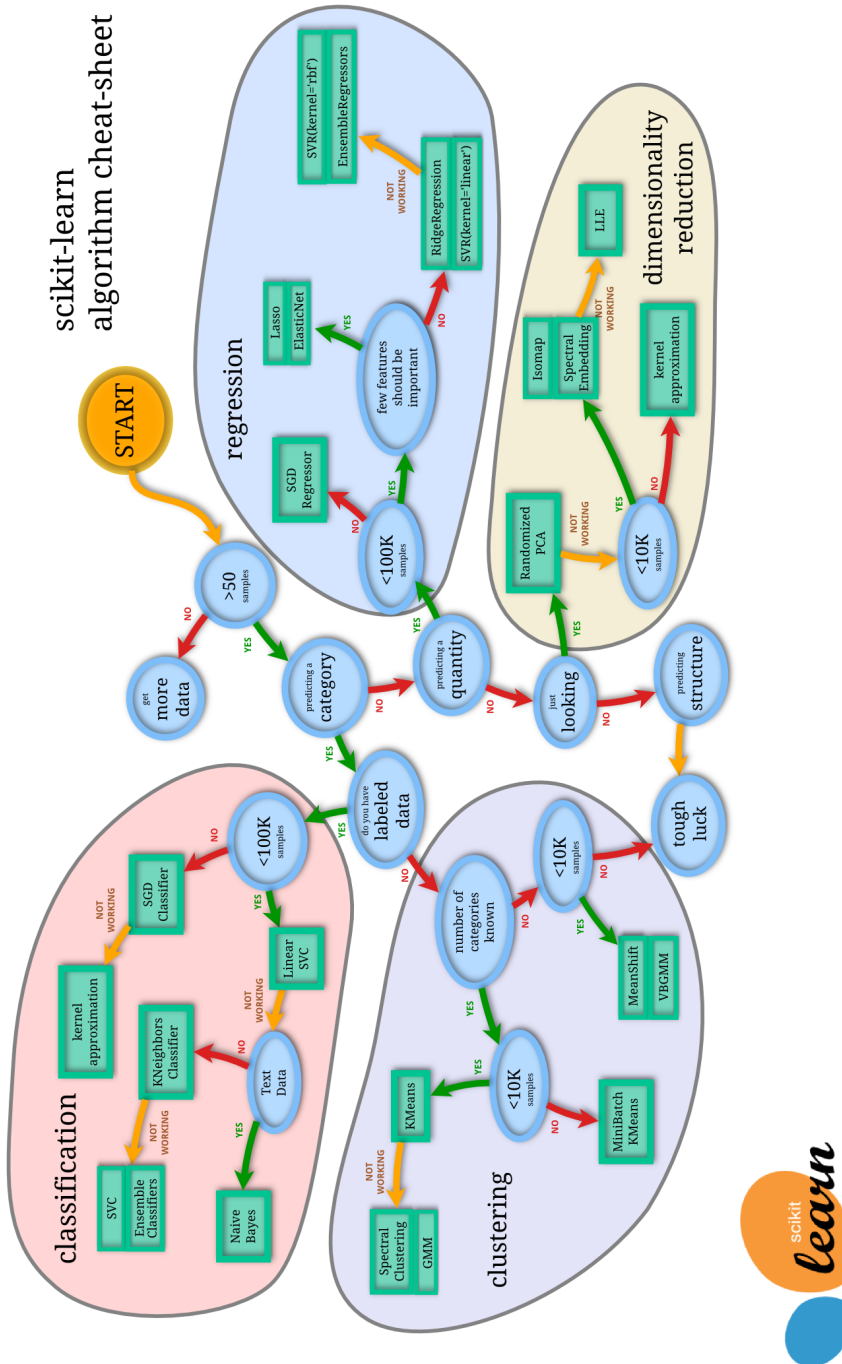

Figure 1: Machine learning algorithm selection diagram for scikit-learn.

usually the biggest one and you use it to build the model. The validation and test sets are roughly the same size, much smaller than the size of the training set. The learning algorithm cannot use examples from these two subsets to build a model. This is why those two sets are often called **hold-out sets**.

There's no optimal proportion to split the dataset into these three subsets. In the past, the rule of thumb was to use 70% of the dataset for training, 15% for validation and 15% for testing. However, in the age of big data, datasets often have millions of examples. In such cases, it could be reasonable to keep 95% for training and 2.5%/2.5% for validation/testing.

You may wonder, what is the reason to have three sets and not one. The answer is simple: when we build a model, what we do not want is for the model to only do well at predicting labels of examples the learning algorithms has already seen. A trivial algorithm that just memorizes all training examples and then uses the memory to "predict" their labels will make no mistakes when asked to predict the labels of the training examples, but such an algorithm would be useless in practice. What we really want is that our model predicts well examples that the learning algorithm didn't see. So we want a good performance on a hold-out set.

Why do we need two hold-out sets and not one? We use the validation set to 1) choose the learning algorithm and 2) find the best values of hyperparameters. We use the test set to assess the model before delivering it to the client or putting it in production.

5.4 Underfitting and Overfitting

We mentioned above the notion of **bias**. We said that a model has a low bias if it predicts well the labels of the training data. If the model makes many mistakes on the training data we say that the model has a *high bias* or that the model **underfits**. So, underfitting is the inability of the model to predict well the labels of the data it was trained on. There could be several reasons for underfitting, the most important of which are:

- your model is too simple for the data (for example a linear model can often underfit);
- the features you engineered are not informative enough.

The first reason is easy to illustrate in the case of one-dimensional regression: the dataset can resemble a curved line, but our model is a straight line. The second reason can be illustrated like this: let's say we want to predict whether a patient has cancer, and the features we have are height, blood pressure, and heart rate. These three features are clearly not good predictors for cancer so our model will not be able to learn a meaningful dependency between these features and the label.

The solution to the problem of underfitting is, evidently, to try a more complex model or to engineer features with a higher predictive power.

Overfitting is another problem a model can exhibit. The model that overfits predicts very well the training data but poorly the data from at least one of the two hold-out sets. We

Figure 2: Examples of underfitting (linear model), good fit (quadratic model), and overfitting (polynomial of degree 15).

already gave an illustration of overfitting in Chapter 3. Several reasons can lead to overfitting, the most important of which are:

- **your model is too complex for the data** (for example a very tall decision tree or a very deep or wide neural network often overfit);
- **you have too many features but a small number of training examples.**

In the literature, you can find another name for the problem of overfitting: the problem of high variance. This term comes from statistics. The variance is an error of the model due to its sensitivity to small fluctuations in the training set. This means that if your training data was sampled differently, the learning would result in a significantly different model. Which is why the model that overfits performs poorly on the test data: test and training data are sampled from the dataset independently of one another.

Several solutions to the problem of overfitting are possible:

1. Try a simpler model (linear instead of polynomial regression, or SVM with a linear kernel instead of RBF, a neural network with fewer layers/units).
2. Reduce the dimensionality of examples in the dataset (for example, by using one of the dimensionality reduction techniques discussed in Chapter 9).
3. Add more training data, if possible.
4. Regularize the model.

Fig. 2 illustrates a one-dimensional dataset for which a regression model underfits, fits well and overfits the data.

Regularization is the most widely used approach to prevent overfitting.

5.5 Regularization

Even the simplest model, such as linear, can overfit the data. This usually happens when the data is high-dimensional but the number of training examples is relatively low. In fact, when feature vectors are very high-dimensional, the linear learning algorithm can build a model that assigns non-zero values to most dimensions $w^{(j)}$ in the parameter vector \mathbf{w} , trying to find very complex relationships between all available features to predict labels of training examples perfectly.

Such a complex model will most likely predict poorly the labels of the hold-out examples. This is because by trying to perfectly predict labels of all training examples, the model will also learn the idiosyncrasies of the training set: the noise in the values of features of the training examples, the sampling imperfection due to the small dataset size, and other artifacts extrinsic to the decision problem in hand but present in the training set.

Regularization is an umbrella-term that encompasses methods that force the learning algorithm to build a less complex model. In practice, that often leads to slightly higher bias but significantly reduces the variance. This problem is known in the literature as the **bias-variance tradeoff**.

The two most widely used types of regularization are called **L1 regularization** and **L2 regularization**. The idea is quite simple. To create a regularized model, we modify the objective function by adding a penalizing term whose value is higher when the model is more complex.

For simplicity, we will illustrate regularization using the example of linear regression. The same principle can be applied to a wide variety of models.

Recall the linear regression objective we want to minimize:

$$\min_{\mathbf{w}, b} \frac{1}{N} \sum_{i=1}^N (f_{\mathbf{w}, b}(\mathbf{x}_i) - y_i)^2. \quad (2)$$

An L1-regularized objective will look like this:

$$\min_{\mathbf{w}, b} C|\mathbf{w}| + \frac{1}{N} \sum_{i=1}^N (f_{\mathbf{w}, b}(\mathbf{x}_i) - y_i)^2, \quad (3)$$

where $|\mathbf{w}| \stackrel{\text{def}}{=} \sum_{j=1}^D |w^{(j)}|$ and C is a hyperparameter that controls the importance of regularization. If we set C to zero, the model becomes a standard non-regularized linear regression model. On the other hand, if we set to C to a high value, the learning algorithm will try to set most $w^{(j)}$ to a very small value or zero to minimize the objective, the model will become very simple which can lead to underfitting. Your role as the data analyst is to find such a value of the hyperparameter C that doesn't increase the bias too much but reduces the overfitting to a level reasonable for the problem in hand. In the next section, we will show how to do that.

An L2-regularized objective will look like this:

$$\min_{\mathbf{w}, b} C \|\mathbf{w}\|^2 + \frac{1}{N} \sum_{i=1}^N (f_{\mathbf{w}, b}(\mathbf{x}_i) - y_i)^2, \text{ where } \|\mathbf{w}\|^2 \stackrel{\text{def}}{=} \sum_{j=1}^D (w^{(j)})^2. \quad (4)$$

In practice, L1 regularization produces a **sparse model**, a model that has most of its parameters (in case of linear models, most of $w^{(j)}$) equal to zero (provided the hyperparameter C is large enough). So L1 makes **feature selection** by deciding which features are important for prediction and which are not. This can be useful in case you want to increase model explainability. However, if your only goal is to maximize the performance of the model on the hold-out data, then L2 usually gives better results. L2 also has the advantage of being differentiable, so gradient descent can be used for optimizing the objective function.

L1 and L2 regularization methods are also combined in what is called **elastic net regularization** with L1 and L2 regularizations being special cases. You can find in the literature the name *ridge regularization* for L2 and *lasso* for L1.

In addition to being widely used with linear models, L1 and L2 regularization are also frequently used with neural networks and many other types of models, which directly minimize an objective function.

Neural networks also benefit from two other regularization techniques: **dropout** and **batch-normalization**. There are also non-mathematical methods that have a regularization effect: **data augmentation** and **early stopping**. We talk about these techniques in Chapter 8.

5.6 Model Performance Assessment

Once we have a model which our learning algorithm has built using the training set, how can we say how good the model is? We use the test set to assess the model.

The test set contains the examples that the learning algorithm has never seen before, so if our model performs well on predicting the labels of the examples from the test set, we say that our model *generalizes well* or, simply, that it's good.

To be more rigorous, machine learning specialists use various formal metrics and tools to assess the model performance. For regression, the assessment of the model is quite simple. A well-fitting regression model results in predicted values close to the observed data values. The **mean model**, which always predicts the average of the labels in the training data, generally would be used if there were no informative features. The fit of a regression model being assessed should, therefore, be better than the fit of the mean model. If this is the case, then the next step is to compare the performances of the model on the training and on the test data.

To do that, we compute the mean squared error³ (MSE) for the training, and, separately,

³Or any other type of loss function you used to build your optimization problem.

for the test data. If the MSE of the model on the test data is *substantially higher* than the MSE obtained on the training data, this is a sign of overfitting. Regularization or a better hyperparameter tuning could solve the problem. The meaning of “substantially higher” depends on the problem in hand and has to be decided by the data analyst jointly with the decision maker/product owner who ordered the model.

For classification, the things are a little bit more complicated. The most widely used metrics and tools to assess the classification model are:

- confusion matrix,
- accuracy,
- cost-sensitive accuracy,
- precision/recall, and
- area under the ROC curve.

To simplify the illustration, I will use a binary classification problem. Where necessary, I will show how to extend the approach to the multiclass case.

5.6.1 Confusion Matrix

The **confusion matrix** is a table that summarizes how successful the classification model is at predicting examples belonging to various classes. One axis of the confusion matrix is the label that the model predicted, and the other axis is the actual label. In a binary classification problem, there are two classes. Let’s say, the model predicts two classes: “spam” and “not_spam”:

	spam (predicted)	not spam (predicted)
spam (actual)	23 (TP)	1 (FN)
not spam (actual)	12 (FP)	556 (TN)

The above confusion matrix shows that of the 24 examples that actually were spam, the model correctly classified 23 as spam. In this case, we say that we have **23 true positives** or $TP = 23$. The model incorrectly classified 1 example as not spam. In this case we have **1 false negative**, or $FN = 1$. Similarly, of 568 examples that actually were not spam, 556 were correctly classified (556 **true negatives** or $TN = 556$) and 12 were incorrectly classified (12 **false positives**, $FP = 12$).

The confusion matrix for multiclass classification has as many rows and columns as there are different classes. It can help you to determine mistake patterns. For example, a confusion matrix could reveal that a model trained to recognize different species of animals tends to mistakenly predict “cat” instead of “panther”, or “mouse” instead of “rat”. In this case, you can decide to add more labeled examples of these species to help the learning algorithm to “see” the difference between them. Alternatively, you can decide to add additional features

the learning algorithm can use to build a model that would better distinguish between these species.

Confusion matrices can be used to calculate two important performance metrics: **precision** and **recall**.

5.6.2 Precision/Recall

The two most frequently used metrics to assess the model are **precision** and **recall**. **Precision** is the ratio of correct positive predictions to the overall number of positive predictions:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}.$$

Recall is the ratio of correct positive predictions to the overall number of positive examples in the test set:

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}.$$

To understand the meaning and importance of precision and recall for the model assessment it is often useful to think about the prediction problem as the problem of research of documents in the database using a query. The precision is the proportion of relevant documents in the list of all returned documents. The recall is the ratio of the relevant documents returned by the search engine to the total number of the relevant documents that could have been returned.

In the case of the spam detection problem, we want to have high precision (we want to avoid making mistakes by detecting that a legitimate message is a spam) and we are ready to tolerate lower recall (we tolerate some spam messages in our inbox).

Almost always, in practice, we have to choose between a high precision or a high recall. It's usually impossible to have both. We can achieve either of the two by various means:

- by assigning a higher weight to messages with spam (the SVM algorithm accepts weights of classes as input);
- by tuning hyperparameters such that the precision or recall on the validation set are maximized;
- by varying the decision threshold for algorithms that return probabilities of classes; for instance, if we use logistic regression or decision tree, to increase precision (at the cost of a lower recall) we can decide that the prediction will be positive only if the probability returned by the model is higher than 0.9.

Even if precision and recall are defined for the binary classification case, you can always use it to assess a multiclass classification model. To do that, first select a class for which you

want to assess these metrics. Then you consider all examples of the selected class as positives and all examples of the remaining classes as negatives.

5.6.3 Accuracy

Accuracy is given by the number of correctly classified examples divided by the total number of classified examples. In terms of the confusion matrix, it is given by:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}. \quad (5)$$

Accuracy is a useful metric only in cases when errors in predicting all classes are equally important. In case of the spam/not spam, this may not be the case. For example, you would tolerate false positives less than false negatives. A false positive in spam detection is the situation in which your friend sends you an email, but the model labels it as spam and doesn't show you. On the other hand, the false negative is less of a problem: if your model doesn't detect a small percentage of spam messages, it's not a big deal.

5.6.4 Cost-Sensitive Accuracy

To deal with the situation in which different classes have different importance, a useful metric is **cost-sensitive accuracy**. To compute a cost-sensitive accuracy, you first assign a cost (a positive number) to both types of mistakes: FP and FN. You then compute the counts TP, TN, FP, FN as usual and multiply the counts for FP and FN by the corresponding cost before calculating the accuracy using eq. 5.

5.6.5 Area under the ROC Curve (AUC)

The ROC curve (ROC stands for “receiver operating characteristic”, the term comes from radar engineering) is a commonly used method to assess the performance of classification models. ROC curves use a combination the true positive rate (the proportion of positive examples predicted correctly, defined exactly as **recall**) and false positive rate (the proportion of negative examples predicted incorrectly) to build up a summary picture of the classification performance.

The true positive rate and the false positive rate are respectively defined as,

$$\text{TPR} = \frac{\text{TP}}{(\text{TP} + \text{FN})} \text{ and } \text{FPR} = \frac{\text{FP}}{(\text{FP} + \text{TN})}.$$

ROC curves can only be used to assess classifiers that return some confidence score (or a probability) of prediction. For example, logistic regression, neural networks, and decision trees (and ensemble models based on decision trees) can be assessed using ROC curves.

To draw a ROC curve, we first discretize the range of the confidence score. If this range for our model is $[0, 1]$, then we can discretize it like this: $[0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1]$. Then, we use each discrete value as the prediction threshold and predict the labels of examples in our dataset using our model and this threshold. For example, if we want to compute TPR and FPR for the threshold equal to 0.7, we apply the model to each example, get the score, and, if the score is higher than or equal to 0.7, we predict the positive class, otherwise, we predict the negative class.

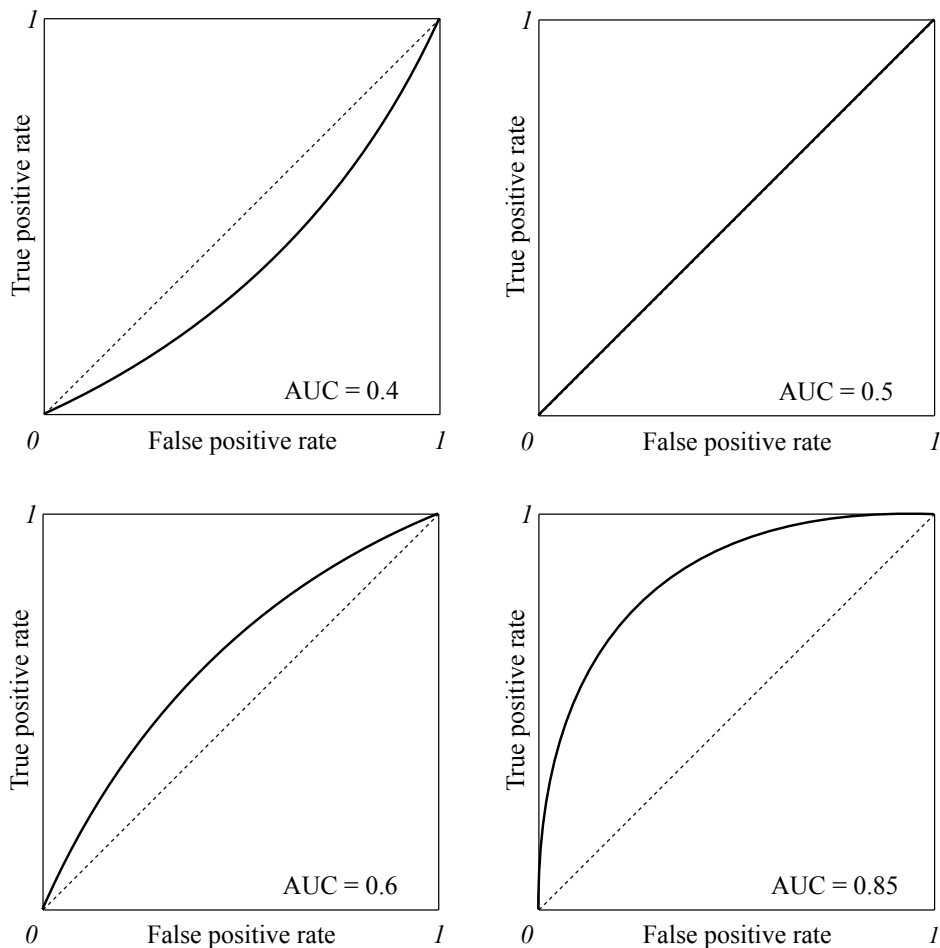

Figure 3: Area under the ROC curve.

Look at the illustration in fig. 3. It's easy to see that if the threshold is 0 all our predictions will be positive, so both TPR and FPR will be 1 (the upper right corner). On the other hand, if the threshold is 1, then no positive prediction will be made, both TPR and FPR will be 0 which corresponds to the lower left corner.

The higher the **area under the ROC curve** (AUC), the better the classifier. A classifier with an AUC greater than 0.5 is better than a random classifier. If AUC is lower than 0.5 then something is wrong with your model. A perfect classifier would have an AUC of 1. Usually, if our model behaves well, we obtain a good classifier by selecting the value of the threshold that gives TPR close to 1 while keeping FPR near 0.

ROC curves are widely used because they are relatively simple to understand, they capture more than one aspect of the classification (by taking both false positives and false negatives into account) and allow visually and with low effort comparing the performance of different models.

5.7 Hyperparameter Tuning

When we presented learning algorithms, we mentioned that you as a data analyst have to select good values for the algorithm's hyperparameters, such as ϵ and d for ID3, C for SVM, or α for gradient descent. But what does that exactly mean? Which value is the best and how to find it? In this section, we answer these important questions.

As you already know, hyperparameters aren't optimized by the learning algorithm itself. The data analyst has to "tune" hyperparameters by experimentally finding the best combination of values, one per hyperparameter.

One typical way to do that, when you have enough data to have a decent validation set (in which each class is represented by at least a couple of dozen examples) and the number of hyperparameters and their range is not too large is to use **grid search**.

Grid search is the most simple hyperparameter tuning strategy. Let's say you train an SVM and you have two hyperparameters to tune: the penalty parameter C (a positive real number) and the kernel (either "linear" or "rbf").

If it's the first time you are working with this dataset, you don't know what is the possible range of values for C . The most common trick is to use a logarithmic scale. For example, for C you can try the following values: [0.001, 0.01, 0.1, 1.0, 10, 100, 1000]. In this case you have 14 combinations of hyperparameters to try: [(0.001, "linear"), (0.01, "linear"), (0.1, "linear"), (1.0, "linear"), (10, "linear"), (100, "linear"), (1000, "linear"), (0.001, "rbf"), (0.01, "rbf"), (0.1, "rbf"), (1.0, "rbf"), (10, "rbf"), (100, "rbf"), (1000, "rbf")].

You use the training set and train 14 models, one for each combination of hyperparameters. Then you assess the performance of each model on the validation data using one of the metrics we discussed in the previous section (or some other metric that matters to you). Finally, you keep the model that performs the best according to the metric.

Once you have found the best pair of hyperparameters, you can try to explore the values close to the best ones in some region around them. Sometimes, this can result in an even better model.

Finally, you assess the selected model using the test set.

As you could notice, trying all combinations of hyperparameters, especially if there are more than a couple of them, could be time-consuming, especially for large datasets. There are more efficient techniques, such as **random search** and **Bayesian hyperparameter optimization**.

Random search differs from grid search in that you no longer provide a discrete set of values to explore for each hyperparameter; instead, you provide a statistical distribution for each hyperparameter from which values are randomly sampled and set the total number of combinations you want to try.

Bayesian techniques differ from random or grid search in that they use past evaluation results to choose the next values to evaluate. The idea is to limit expensive optimization of the objective function by choosing the next hyperparameter values based on those that have done well in the past.

There are also **gradient-based techniques**, **evolutionary optimization techniques** and other algorithmic hyperparameter tuning techniques. Most modern machine learning libraries implement one or more such techniques. There are also hyperparameter tuning libraries that can help you to tune hyperparameters of virtually any learning algorithm, including ones you programmed yourself.

5.7.1 Cross-Validation

When you don't have a decent validation set to tune your hyperparameters on, the frequent technique that can help you is called **cross-validation**. When you have few training examples, it could be prohibitive to have both validation and test set. You would prefer to use more data to train the model. In such a case, you only split your data into a training and a test set. Then you use cross-validation to on the test set to simulate a validation set.

Cross-validation works like follows. First, you fix values for hyperparameters you want to evaluate. Then you split your training set into several subsets of the same size. Each subset is called a *fold*. Typically, **five-fold cross-validation is used in practice**. With five-fold cross-validation, you randomly split your training data into five folds: $\{F_1, F_2, \dots, F_5\}$. Each F_k , $k = 1, \dots, 5$ contains 20% of your training data. Then you train five models as follows. To train the first model, f_1 , you use all examples from folds F_2, F_3, F_4 , and F_5 as the training set and the examples from F_1 as the validation set. To train the second model, f_2 , you use the examples from folds F_1, F_3, F_4 , and f_5 to train and the examples from F_2 as the validation

set. You continue building models iteratively like this and compute the value of the metric of interest on each validation set, from F_1 to F_5 . Then you average the five values of the metric to get the final value.

You can use grid search with cross-validation to find the best values of hyperparameters for your model. Once you have found these values, you use the entire training set to build the model with these best values of hyperparameters you have found via cross-validation. Finally, you assess the model using the test set.
